ABSTRACT

Hourly rainfall data from ten representative rainfall stations in Puerto Rico were analyzed to determine storm rainfall characteristics. Spatial and temporal variabilities of storm rainfall were presented.

Storm events were identified objectively. Storm durations for various events were estimated. Mean storm rainfall intensities were found for all historical storms with mean intensities higher than 0.20 in/hr. Non-dimensional storm rainfall distributions were found for all the stations. The distributions were stratified by storm duration and storm class where a class is defined as the portion of the storm with heavier rainfall.

Frequency analyses were performed on storm durations, and storm rainfall intensities. Relevant tendencies were analyzed. Daily rainfall distributions at various stations were developed. Three predominant tendencies were found, namely, skewed uni-modal, bi-modal, and multi-modal distributions.

Frequency analyses of order statistics were done on storm data and hourly data independent of storm events. Relevant discrepancies exist between both analysis. Results show that the intensity-duration-frequency design criteria recommended by the National Weather Service (Technical Paper #42, 1961) need to be updated.

ACKNOWLEDGMENT

This study was supported by the Water Resources Research Institute of the Department of the Interior. Their financial support is greatly appreciated.

The research work was performed at the Department of Civil Engineering of the Mayaguez Campus. Computer facilities of the University Computer Center were intensively used during the project. The computer center personnel kindly helped advising throughout the research work.

The writer also appreciate the administrative efforts and support given by Dr. Rafael Muñoz, Associate Dean of the School of Engineering and Director of the Engineering Research Center.

Walter Silva, graduate research assistant at the Department of Civil Engineering was incharged of programming computer algorithms. He also managed rainfall data. His efforts in this study are highly qualified for a graduate research assistant. His cooperation and professional efficiency are highly appreciated.

Héctor Rivera, undergraduate student of the Department of Electrical Engineering efficiently helped in the frequency analysis and advised in the use of computer facilities.

José Roubert, Ernesto Arroyo, and Jorge Tirado, research assistants in the Department of Civil Engineering, helped in developing graphs, figures, and running computer programs.

Sarita Feliciano, Aida Feliciano and Carmen Muñiz, secretaries of the Engineering Research Center helped typing the final draft of the final report.

Other people who, in one or other way, cooperated with the writer were Mr. Ferdinand Quiñones, Director of the Caribbean Office of the USGS;

Dr. José A. Colón, Director of the San Juan Weather Forecast Office (SJWFO); Mr. Robert Calvesbert, Hydrologist of the SJWFO; and Prof. Julio Ríos of the Department of Civil Engineering at Mayaguez Campus.

Last, but not least, the writer is deeply indebted with his wife and daughters for their continuous support and patience.

The accomplishment of the research work presented herein has been the cooperative effort of all the people who got involved in any way in the project. To all of them, the writer's most sincere appreciation.

1. Introduction

Precipitation can be considered as the driving mechanism of the hydrologic cycle. Although many types of precipitation exist, rainfall is the only relevant one in Puerto Rico.

Rainfall is associated with storm events. The research work discussed herein is the first comprehensive effort guided to evaluate hourly rainfall data collected by the National Weather Service Office with the purpose of describing statistical characteristics of tropical rainstorm events in Puerto Rico.

Storm sewer, culvert, street and urban drainage, agricultural drainage, and channel design are all sensitive to the characteristics of rainstorm events. Moreover, the hydrology and hydraulics of small watersheds highly depend on rainstorm characteristics. Flash floods are the typical response of small but steep watersheds in Puerto Rico. Variabilities in the rainfall input cause great changes in watershed responses. Therefore rainfall-runoff analysis design is highly affected by storm rainfall characteristics. Rainstorm modeling and simulation require a good knowledge of the rainfall distribution in time and space.

Safety, risk and economic analyses depend on accurate estimation of storm rainfall variabilities. Weather modifications such as those produced by urban development, industrial activities, air flight traffic, and induced rainfall activities can be evaluated utilizing changes in storm rainfall distributions. Flood and weather forecasting are dependent on the accuracy of modelling the climate and rainfall-runoff dynamics. Both are affected by the spatial and temporal rainfall characteristics. Optimum management of water resources for small communities is sensitive to rainstorm occurrence. Reservoir operations and aquifer recharge basi-

cally depends on the intensity, location, distribution, and frequency of storm events.

Hydrologic and hydraulic design are affected by the spatial and temporal rainfall variabilities in Puerto Rico. A statistical analysis of the hourly rainfall record available should provide valuable information in terms of the spatial and temporal rainstorm characteristics. The spatial and temporal distribution of point duration, and effective time raining are among the significant characteristics that we can studied in order to provide a significant evaluation of the storm rainfall.

Considering that there exist limited information inferred from real data analysis, the research project discussed herein promise to contribute remarkably to the understanding of storm rainfall inputs in hydrologic and hydraulic analysis, simulation, modelling and design. Also, this research effort opens a window for further studies in rainfall as frequency analysis, rainfall-runoff relationships, long term (monthly, annual, seasonal) and short term (15 minutes) rainfall characteristics, antecedent moisture conditions, and other rainfall related studies.

The specific objectives of the research work discussed herein are to:

1. Objectively define and select representative rainstorm events in Puerto Rico.
2. Determine non-dimensional temporal storm rainfall distributions
3. Determine variabilities of storm rainfall distributions with storm duration, location, and other relevant parameters.
4. Determine probability density functions of storm durations and intensities.
5. Interpolate geographically temporal storm rainfall distributions.

2. Related Research

The spatial and temporal rainfall variabilities in Puerto Rico are practically unknown. However, it is known that rainfall varies considerably either in space or time. Rainfall in Puerto Rico is associated with either of the following mechanisms: 1) easterly waves which basically occur during summer season (May-November months) or, 2) cold fronts which are associated with the winter season (December-April months). Easterly waves as tropical disturbances usually involve torrential rain. Otherwise, they bring near normal rainfall. Cold fronts are associated with cold air masses coming from the north which occasionally move far enough south to reach the Caribbean. Active slow moving cold fronts may produce storms of moderate intensities which last intermittently for several days.

In the island also exist a remarkable orographic effect which induce more rainfall generation and affects the spatial and temporal rainfall distribution. It produces larger rainfall amounts in the northern and mountain than in the southern regions. Convective effects produced by differential heating in urbanized metropolitan areas may also affect the rainfall pattern. Saturated air masses heated over developed areas are lifted to colder levels where condensation and precipitation occur.

The highly variable rainfall distribution in the island is caused by complex rainfall generation mechanisms which frequently interact among themselves. Modelling these rainfall phenomena is a difficult task specially when neither the physical mechanisms producing rainfall nor the rainfall characteristics on the ground are clearly defined in Puerto Rico.

The best attempt of describing the spatial and temporal rainfall variabilities of storm rainfall was conducted by the National Weather

Bureau (NWB, 1961). The published hydrologic design maps for Puerto Rico and Virgin Islands. Probable maximum precipitation (PMP), depth-duration-frequency rainfall, and cloudburts rainfall were analyzed and presented. Durations of 30 minutes to 24 hours for frequencies of 1, 2, 5, 10, 25, 50 and 100 years were given for rainstorms. PMP for durations of 1, 6, and 24 hrs were provided. Also, PMP for cloudbursts of durations between 5 minutes and 6 hours were given. A similar effort was done later (Miller, 1965) providing PMP amounts for rainstorms of duration from 1 to 10 days.

Although these publications have been the unique tool for selecting desing storms in Puerto Rico, they do not provide criteria for slecting either the storm frequency and duration, or a satisfactory storm rainfall distribution in time. The papers suggest criteria for slecting the hourly distribution of the PMP storm. It also suggests to use the most critical temporal rainfall distribution for PMP cloudbursts. There is neither evi-dence for the former nor justification for the latter. Engineering ana-lysis, simulation modelling, and design require realistic criteria for the selection of rainfall variabilities in time and space. It could be better inferred from the analysis of existing storm rainfall data.

The practice in Puerto Rico has been to transfer rainfall analysis and design criteria from other geographical locations, specially those derived form the United States. Oxford (1969) recognized the inadequacy of rainfall data for pavement drainage design in San Juan, Puerto Rico. He used cloudburst rainfall as critical design condition. Although he shows no documentation for selecting a rainstorm duration of 15 minutes and a frequency of approximately 1/10 of the PMP for cloudbursts, he clearly shows the need for defining storm rainfall characteristics in

time and space in order to provide realistic criteria designing purposes.

Storm intensity, duration, and frequency in time and space are the most important paramter in rainfall analysis for short term rainfall-runoff relationship. Other than Technical Paper #42 and #53, (NWB, 1961; Miller, 1965) the writer has found no significant contribution on this topic in Puerto Rico.

In a major effort to corroborate his findings, he has consulted the National Weather Service in San Juan, Puerto Rico, searching for published or unpublished literature (Colón, 1983). An effort has been done by the National Weather Service Flash Flood Hydrologist to evaluate the NWB Technical Paper # 42 (Calbeberst, 1953). He has found remarkable discrepancies on a station analysis basis. Detailed frequency analysis in Puerto Rico is under way by ongoing research project directed by the writer. Although it is beyond the scope of this research work to perform analysis of order statistics, limited results are presented for the convenience of the reader.

Design storms generally are selected for duration equal to the time of concentration of the basin. Small watersheds usually have time of concentration of less than 6 hours. For example, the Soil Conservation Service recommends to use the larger between the time of concentration of a basin or the 6-hr duration event, whichever longer, for the design of emergency and freeboard hydrographs of small dams. (Viessman, et al., 1977).

Duration of desing storms should be selected on a probability base. Even when the basin shows a long time of concentration, the probability of having a storm duration equal to the time of concentration can be very low. Therefore, there is no justification for designing for a duration

equal to the time of concentration. A better way is to design for the storm duration which minimize cost of failures.

Selecting representative hydrographs once the storm depth and duration have been selected is the last step in defining the design storm. Temporal distribution of the design storm will significantly affect the watershed response as the shape and peak value of the hydrograph.

Temporal storm rainfall distributions needed to be developed for the hydrometeorological condition of local areas. Transferring storm rainfall distribution from other places is not an acceptable practice unless both areas show similar hydrometeorological characteristics. For example, the Soil Conservation Service Type II storm rainfall distribution has been recommended frequently en Puerto Rico. It is sensitive and risky not to verify and update these type of criteria, specially when the risk of a project failure due to undocumented criteria is high.

The importance of rainfall analysis has been well acknowledged. Similar studies to the one proposed herein have been conducted by the Illinois State Water Survey during the past decade. Their studies have been broad in their goals including weather modifications studies, agricultural problems, urban drainage design, water quality, and real time weather and flood forecasting (Acherman, et al., 1977; Changnon, et al., 1978). These studies provide rainfall analysis and design criteria for the midwestern region of the United States, therefore, they do not apply here. However, it is important to point out that they have succeed in their effort of providing rational and practical rainfall criteria for analyses, simulation, modelling, and design in hydrology and hydraulics.

3. Research Procedures and Methodologies

3.1 Data Manipulation

3.1.1 Data Acquisition

Hourly rainfall data collected by the U. S. National Weather Service (NWS) and published in computer magnetic tapes by the Environmental Data Service, National Climatic Center, U. S. Department of Commerce at Ashville, North Carolina was used in the research work discussed herein.

3.1.2 Data Selection

The data selected for the study included 10 out of 29 rainfall stations reported for Puerto Rico and Virgin Islands. Table 3.1 presents a brief description of the stations selected. It includes station name, index number, location, length of rainfall record, and total number of storm events recored at the station. Figure 3.1 shows the approximate location of the selected stations in the study.

Although it is desirable to use all the available rainfall stations for determining detailed spatial rainfall characteristics, the stations selected were considered representative of major spatial storm rainfall characteristic trends in the island. Multiplicative efforts introduced by considering extra stations limited the number of representative stations to 10.

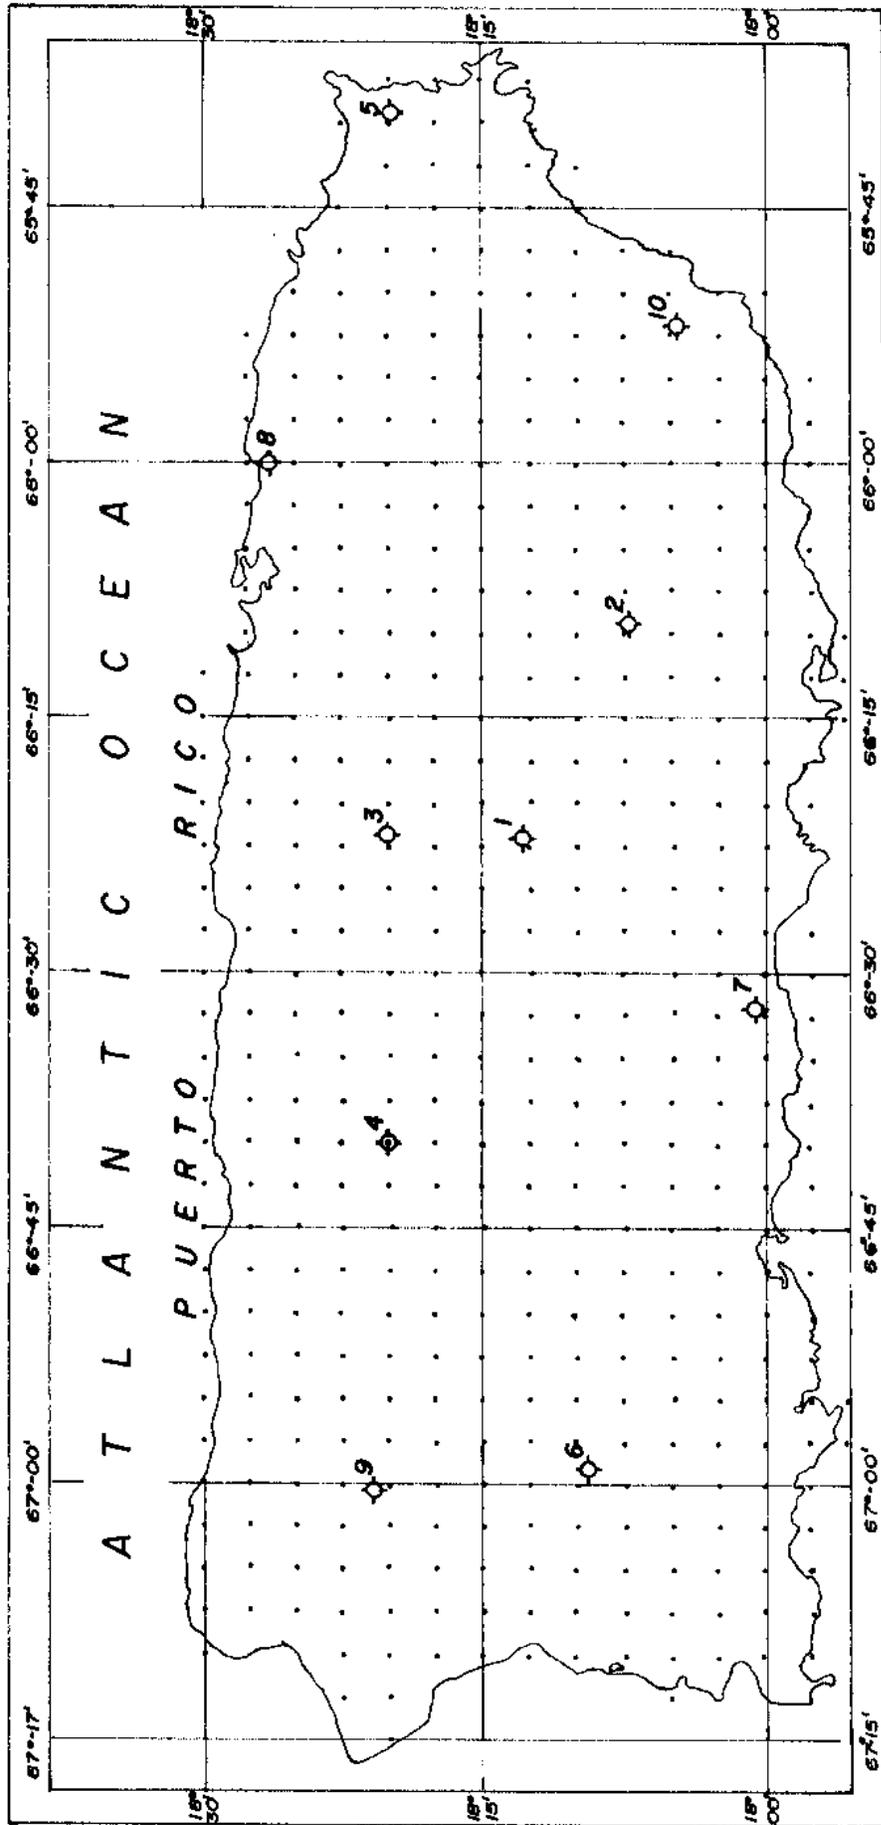

A maximum record length of 204 months was available at San Juan station. The minimum record length is of 121 months is Botijas 2-Orocovis station. Record length available in Puerto Rico are not the most desirable for obtaining high statistical significance in every hydro-

logic application. However, valuable information is derived and inferred from actual field data. It will help in achieving rational and practical analysis and design in hydrology.

Missing and accumulated rainfall values were not used in this research work.

3.1.3 Objective Storm Definitions

Pagán-Trinidad (1982) has suggested various objective storm event definitions. A storm can be defined from either the meteorologic or the engineering viewpoint. In meteorology a storm is recognized by its atmospheric physical properties as three dimensional and turbulent process which can be modeled by means of heat and mass transport theory. Therefore, the meteorologists frequently define a storm system based on its spatial and temporal boundary characteristics along with the synoptic pattern. Conversely, from the engineering viewpoint, a storm is generally defined based on the duration of the recorded event at one or more points within an area.

3.1.3.1 Meteorologic Definition of Storm

The precipitation process is mainly caused by dynamic or adiabatic cooling which involves a vertical transport of saturated air masses. Therefore, the hydrometeorologists have classified it based on the mechanism causing the vertical displacement as convective, orographic or cyclonic precipitation. Although meteorologists have more specific characterization of synoptic storm patterns

based on the storm physical properties, it suffices engineering applications the classification based on the storm cooling mechanism. The latter classification is more meaningful to engineers because it better shows the expected rainfall characteristics on the ground. Spatial and temporal regularities have been observed in rainfall of similar cooling mechanisms. They are described in the following.

3.1.3.1.1 Convective Precipitation

Convective precipitation is caused by heating and lifting of saturated air masses near the ground surface. The air mass expands as it rises and reduces its density. A vertical motion follows reaching a level where cooling, condensation and precipitation follow. Short, spotty, and extremely intense thunderstorms are typical under this classification.

3.1.3.1.2 Orographic Precipitation

Orographic precipitation is caused by mechanical lifting of warm saturated air masses due to physical constraints like mountains. The air masses are pushed into a cooler level where cooling, condensation and precipitation occur.

3.1.3.1.3 Cyclonic Precipitation

Cyclonic precipitation is associated with the large scale vortex type motion which is caused by air masses of different energy content. Air masses are forced to flow due to the pressure difference causing the warmer air to

override the cool air. It is characterized for being less intense and covers larger areas than the convective type. Cyclonic precipitation could be classified as frontal or non-frontal. A front is the boundary between both air masses. In a cold front the cold air wedge advances into the warm air mass forcing it upward rapidly causing intense storms along the front. In a warm front the warm air flows over the cold air. It ascends and moves slower than the cold front causing less intense precipitation over larger areas with relative long duration.

3.1.3.2 Engineering Definition of Storm

The storm definition from the engineering viewpoint is generally based on the recorded duration of the storm at a point or an areal basis. The point concept needs to be extrapolated to an areal concept in order to have a consistent physical picture of the process. Several possible storm duration definitions based on point precipitation data is presented as follows.

3.1.3.2.1 Point Definition of Storm

1. Continuous wet period - The storm duration is defined by the continuous raining period at a given station. If the data is given in discrete time intervals (e. g., hourly data), the storm duration is highly dependent on the sampling time interval. The possible error of having a dry period within the duration of almost twice the discrete time interval could pass undetected.

2. Wet-dry periods - The storm duration is defined by the wet-dry period which contains no dry period longer than a selected duration, e. g., Huff (1967) selected 6 hours as the optimum time to differentiate between storms events.

3. Auto-correlation - A storm duration is defined by the time lag k which minimizes the first cycle of the rainfall correlogram.

3.1.3.2.2 Areal Definition of Storm

1. Total area wet - A storm is defined by the length of time when all stations within an area record rainfall. This definition has the same deficiency at the point definition presented in addition to its dependence on the size of the area. Also there is no way of excluding dry subareas between station. It also excludes the partial area events.

2. Partial area wet - A storm is defined by the time when at least one station within the area records rainfall.

3. Wet-dry area - A storm duration is defined by the continuous time which does not contain a dry period in the whole area for a time interval longer than a selected duration.

4. Wet-dry-period - A storm duration is defined by the wet-dry period which contains no dry period in any single station within the area longer than a selected duration.

3.2 Development of Temporal Storm Rainfall Distributions

The engineering concept of defining storm events at a point was used herein. Continuous raining periods were selected from the data. Storm duration, rainfall depth, and mean rainfall intensity were determined each storm and for each stations analyzed. Significant storm events were limited to those showing storm rainfall intensities grater or equal to 0.20 in/hr.

Similarly, storm events were selected for a maximum non-rainy (dry) period between rainy (wet) period of 3 hours and 6 hours. Probability density functions were also found for these two criteria.

Once storm events were selected and identified the following was performed at each rainfall stations for continuous storm rainfall events.

1. Cumulative dimensional hydrographs were found by adding incremental rainfall depths by hour.
2. Cumulative dimensional hydrographs were non-dimensionalized by converting storm time to percent of total storm duration, and rainfall depth to percent of total rainfall depth for each storm event.
3. Storm evetns were stratified by storm duration.
4. Storm evetns for each duration were stratified by storm class depending on the period when the maximum rainfall felt. The periods were defined as shown in Table 3.2.

Table 3.2 Criteria for Defining Storm Duration Class
Based on the Period of Maximum Rainfall

Storm Duration (hours)	Criterion
2	media
3	tercile
4 - 6	quartile
7 - 12	quartile

5. Mean non-dimensional storm rainfall distributions were determined by obtaining the mean distributions for each storm duration class (e. g., each quartile). Other basic statistics were obtained for each point estimated in the curve.

6. Non-dimensional storm rainfall distributions were plot for various storm durations shown in Table 3.2.

3.3 Frequency Analysis

Frequency analysis provides the probability of occurrence of determined parameters. Probabilities of storm durations and mean storm rainfall intensities were determined in order to define storm rainfall characteristics. Order statistics for mean storm rainfall intensities of various durations at each station were determined. Order statistics of hourly rainfall data independent of storm event were also found.

3.3.1 Storm Duration

Frequency analysis of storm durations was performed as follows:

1. The relative frequency f of storm duration as stratified in Table 3.2 were obtained for each station by counting the number of storms in each duration class n divided by the total number of storms N .

Mathematically

$$f = n/N \quad (3.1)$$

2. Probability density functions were smoothed out by using variable class intervals in the analysis.
3. Histograms were plot in order to show the trend of probability density functions. The mean value of the probability density functions were used for those class intervals grater than 1 hour.

3.3.2 Mean Storm Rainfall Intensity

Distribution of storm rainfall intensities of 0.10 in/hr beginning with 0.20 in/hr and ending, but not including, 1.0 in/hr. Thereafter, class interals every 0.5 in/hr were used. The following procedure was followed.

1. Storm events were stratified by duration.
Duration clases of 1 hr, 2 hr, 3 hr, 4-6 hr, 7-12 hr events were analyzed.
2. Relative frequencies f of storm rainfall intensities were obtained by counting the number of storms with mean rainfall intensities in each class interval of the selected storm durations.

3. Probability density functions were smoothed out by selecting variable class intervals as described previously.
4. Histograms were plot for each stratification including those for all storm durations together.

3.3.3 Order Statistics

3.3.3.1 Intensity-Duration-Frequency Analysis of Rainstorms

Order statistics were obtained for partial duration series of rainstorm intensities of various durations at each station. The number of events in each sample were conditioned by the total number of events available for each duration. Since continuous storm events were considered, the sample size decreased exponentially as the storm duration increased. Order statistics were obtained no matter the sample size. Since the principal interest of this research work focuses on short duration storm events (e. g., less than 6-hr events), sample sizes are considered suitable. Order statistics were obtained as follows:

1. Exceedance probabilities were obtained by organizing in descending order rainfall intensities for each duration at each station.
2. The probability $P(X \geq x)$ of a given event being equaled or exceeded in any specific year was obtained from the following mathematical relationship,

$$P(X \geq x) = \frac{m}{N} \quad (3.2)$$

where:

m = order rank of the event in the partial duration series

N = total number of years in the record

X = hydrologic variable

x = hydrologic variate

3. The return period T in years was estimated as:

$$T = \frac{1}{P(\geq x)} = \frac{N}{m} \quad (3.3)$$

3.3.3.2 Exceedance Probabilities of Hourly Rainfall Data

Intensity-duration-frequency analysis performed in the previous section is based on mean storm intensities. A selection criteria for considering storms in the sample was a minimum mean rainstorm intensity equal to 0.20 in/hr. This criteria warrants relevant and significant rainstorm events. However, extreme rainburst within rainstorms were not considered as potential extreme events because they are hindered by a longer rainstorm event.

Frequency analysis of extreme hourly rainburst was performed as follows:

1. The total number of hours with rainfall were selected in the sample independent of the storm duration.

2. A partial duration series of hourly rainfall values were organized in descendent order.

3. The probability $P(X \geq x)$ of being equaled or exceeded any specific year was obtained from equation

4. The return period T in years was computed by equation (3.3).

3.4 Data Processing and Reduction

A DECSYSTEM - 10 high speed mainframe computer was mainly used for processing rainfall data. Various computer codes were written in Fortran which performed tasks mentioned previously in this chapter. SPSS software package was used to performed part of the frequency analysis. Software was developed for special cases where SPSS did not apply.

Various microcomputers (e. g., IBM-PC, RAINBOW) were mainly used for developing graphics (e. g., non-dimensional storm rainfall distributions, probability density functions). Micro-computer software was coded in BASIC language for interpolating non-dimensional storm rainfall distributions.

Results were presented in tables, graphs, and computer printouts. Most tables and graphs are incorporated in the report discussed herein. However, valuable computer printouts will be available on request basis. Results will be discussed in the following section.

4. Experimental Results:

Results of this research work are discussed next. Most of the information analyzed have been condensed and reduced to tables and graphs. Details of the research results have been stored in extensive computer files which can be printed out and furnished upon the reader's request.

4.1 Non-Dimensional Temporal Storm Rainfall Distributions

Storm events were selected according to the criteria of 1) minimum times between separate storm events, and 2) minimum mean storm rainfall intensity. Storm events were stratified according to station. Minimum times between storms of 1-hr, 3-hrs, and 6-hrs were used to compare the effects of expected non-raining (dry) periods within storms. The selection of minimum times between storms is a criteria which varies with the type of hydrologic applications. In fact, Viessman (1977) points out that for urban drainage design the storm duration is usually shorter than 6 hrs. In this case, minimum time between storms of 1 hour is sufficient to separate two independent events. Therefore, considering that most of our urban and rural watersheds show time of concentrations of less than 6 hrs, this research work emphasizes the analysis on continuous rainfall periods. Also information is presented for the criterion of 6-hrs minimum time between storms for comparison purposes.

Storm events were selected following the criteria presented previously. Storm durations were estimated. The mean storm rainfall intensities were computed. Storms were stratified according to durations as 1, 2, 3, 4-6, 7-12 duration

events. Storms were also stratified by media, tercile or quartile depending on the portion of time when the maximum amount of rainfall fell. For example, a 2-hr storm experiencing the heavier rainfall during the first 50% of the duration of the storm is classified as a first media storm, a 4-hr storm experiencing the heavier rainfall in the third 25% of the duration is classified as a third quartile storm.

Figures A1 to A10 present non-dimensional storm rainfall distributions for ten rainfall stations analyzed in the study. One figure is presented for each of the durations mentioned previously. One hour storms are not shown because a uniform distribution is expected from hourly rainfall data. These distributions can be achieved utilizing 15-minute rainfall data which is out of the scope of this research work. However, the writer is involved in evaluating short term storm rainfall distribution for durations less or equal to one hour.

One non-dimensional storm rainfall distribution curve is presented for each storm class within the duration. Storm classes were discussed previously in Table 3.2. Figures show approximate continuous distributions which have been approximated from discrete data. Statistics of various points are available for the distributions, however they are too extensive to be included herein. Approximations of continuous curves are based on the writer's experience with thousands of storms analyzed and typical distributions developed elsewhere. The reader is free to approximate the distributions with two linear segments although it is less likely to occur this way and the writer

does not recommend to do so. Distributions have not been smoothed out since the writer will be completing the study by analysing the remaining rainfall station in Puerto Rico. At that time trends will be better determined and smoothing can be done with higher reliability.

Rainstorms of two and three hour durations were discretized according to hours of data in the storm. Rainstorms of 4-6, and 7-12 hr-duration were classified together in order to increase the sample size. In these cases, interpolation were done every 10% and every 25% of storm durations. However storm classes were selected for quartiles. Each media, tercile or quartile distribution is represented by one curve.

Table A1 presents frequency storms per class and frequency of storms per duration at the studied rainfall stations. It was found that there are a significant chance of having uniform storms in 2-hour duration events. The opportunity is negligible for other durations.

The frequency distributions of storm classes show that there are preferential classes for rainstorms to occur. For example, at Botijas 2-Orocovis Station the preference for 2-hr duration events is the first media showing 69 out of 123 storm events or a 56% of the total. Preferential storm classes denoted by the mode of the distribution can be recommended for hydrologic design purposes, although all the possible distributions can be tested in design for sensitivity. Urban drainage is highly sensitive to temporal storm rainfall distributions. Sensitivity analysis of storm rainfall distributions in this case can pro-

vide the most critical operation conditions. The mode of the distribution of storm classes is marked with an asterisk in Table 3.2.

Non-dimensional storm rainfall distributions presented in Figure A1 to A10 show significant temporal storm rainfall variabilities from station to station, and at different durations for the same station. It is significant to point out that the temporal storm rainfall shows that various storms accumulate over 60% of the total storm rainfall in less than 25% of the duration. (e. g., San Juan Station, 4 to 6 hrs; 1st, 2nd, and 3rd quartiles), and all the stations analysis show that in several 2-hr storms over 70% of the total rainfall is accumulated in less than 50% of the storm duration (e. g., 1st quartile storms). This is particularly significant because all the stations show greater number of 2-hr storms in the first media. In general, non-dimensional storm rainfall analysis shows that the tendency is not uniform rainfall distributions within storms, but significant variable ones. Storm rainfall distributions depend mainly on location, storm duration, and storm class.

Spatial variability of distributions from station to station is significantly larger as storm duration increases. Storm durations of 2 and 3 hours show similar patterns.

Although regionalization of storm rainfall distributions can show better spatial variabilities, it may not be the most appropriate way of estimating distribution in ungaged areas.

The temporal storm rainfall distributions at a point are valid for the specific location of the stations. Engineering

applications will require to derived similar distribution at ungage sites. For this purpose an interpolation skeme which utilizes the information available need to be used. Pagán-Trinidad (1982) has presented a detailed analysis of various interpolation schemes with special emphasis on rainfall interpolation. An inverse distance technique is recommended. Orographic effects can be considered by incorporating a modified normal annual precipitaion skeme. Appendix B presents an inverse distance technique to interpolate storm rainfall distribution curves for the any of the storm class distributions. Storm class modes are found in Table A1 for ten stations in Puerto Rico, should that is the recommended distribution,

4.2 Frequency Analyses of Storm Rainfall

Table A2 presents frequency of rainstorms stratified by rainfall intensity and duration for ten selected stations in Puerto Rico for storm criteria of 1-hr minimum time between storms. The analysis was done for all storms together independently of their durations, and for various durations as 1, 2, 3, 4-6, 6-12, rainstorm duration events. Rainfall intensities in in/hr were stratified as shown in the table. The parameters n , f , and F are frequency (numbers of storms per intensity class), relative frequency (n divided by total number of storms shown in last line of the table), and cummulative frequency (Σf).

The table shows interesting tendencies. For a given storm duration the relative frequency (probability) of mean storm intensities are decaying with an increase in the intensity. This is valid for all durations. Storm duration classes grater

6 hours are not considered reliable durations because its limited sample size. The same tendency is equally valid for all the station in the study independently of the number of storms per duration class.

Storm durations also show a decaying patterns as the storm duration increases. Since the table only shows the frequency of storm durations in variable class intervals, it is easier to visualize tendencies plotting histograms of the data in Table A2.

Figures A11 to A20 presents probability distributions of storm rainfall intensities in in/hr per storm duration in hours at the selected stations in Puerto Rico for rainstorms events selected with the criteria of 1 hour between storms. The total number of events is shown at the top of the figures.

Trends and tendencies are better observed by histograms. Histograms for various duration at different stations follow similar patterns. Mathematical equation describing observed tendencies can be derived. For example, an exponential decay function can be well adjusted to the data. Various models will be fitted to the data in a continuing project. An exponential model can be generically stated as:

$$P(i_1 \leq i \leq i_2) = \int_{i_1}^{i_2} i^x \cdot di \quad (4.1)$$

$$\text{or } p(i) = i^x \quad (4.2)$$

where:

$P(i_1 \leq I \leq i_2)$ = probability of variable I

i, i_1, i_2 = intensity variates in in/hr

$p(i)$ = probability density function of i

x = exponent

It is relevant to point out that x values can be used for regionalization purposes for specific durations. At this stage values of x have not been found because it is worth it to consider the remaining stations in Puerto Rico. A continuing effort is being followed by the writer to complete this part of the study.

Similarities of probability density functions at different locations are obvious from the figures. Dispersion of data in high duration events is due to the limited sample size.

Probability distributions for rainstorm durations up to 6 hours at various stations are presented in Figure A21. Rainstorms criterion of 1-hr between storms was used. A similar model to the one discussed previously for rainstorm intensities can be fitted to this data. In this case the model can be stated as:

$$p(D) = D^{-Y} \tag{4.3}$$

where:

p(D) = probability density function of storm duration

D = storm duration in hours

Y = exponent

Similar storm duration distributions were found through the island. Regionalization will be made after further stations are considered. From the previous results it is found that the probability density function can be fitted to a model with storm duration and intensities or independent variables. Therefore, for the generic model of rainstorm intensity

$$x = F(D) \tag{4.4}$$

An attempt to study the effect of the criteria used to

select storm event was done by studying storms with minimum time between storms equal to 6 hours.

Table A3 presents a summary of frequency of rainstorms stratified by rainfall intensities and durations. A merge of short duration storms (e. g., 1, 2, and 3-hr duration rainstorms) is obvious as the frequency of these storms decreases and the those for higher classes increases. The total number of storms is reduced due to the merge of storms into one of longer durations. The relative frequency distributions still follow a similar patterns to the distributions of storms selected by 1-hr minimum time between storms. The increase in the frequency of longer duration storms may serve to increase the sample size of storm durations between 6 an 12 hours.

The number of storm with duration longer than 12 hours is not significant. Therefore it could be concluded that rainstorm events in Puerto Rico tends to last for duration of less than twelve hours. Rainfall events of longer durations are associated with hurricane events. Long duration events show extremely low rainstorms mean intensities.

Figures A22 to A31 show probability density functions of mean storm rainfall intensities for storm selection criteria of 6-hr between storms for the station selected in the study. The functions were stratified by storm rainfall duration as it was done previously. The figures show the data reduction of Table A3. Storm duration distributions are shown in Figure A33.

Results are similar to previous results. The main difference between both criteria is that the distributions are

flattened somehow due to the increase of longer duration events. It is important to notice that both criteria are relevant in engineering hydrologic design and should be applied separately on a case by case basis. Distribution of continuous storms are relevant to hydrologic design of design storm shorter than 6 hours which is generally the case of urban and small watershed hydrology typical in Puerto Rico.

The other criteria can be applied to few relative large basins in Puerto Rico (e. g., Río Añasco basin, Río La Plata basin, Río Grande de Loiza basin).

The daily rainfall distribution at the studied stations were analyzed in order to determined preferred time of rainfall during the day cycle. Hourly rainfall distributions in the day show trends and patrons in the rainfall temporal distribution.

Table A4 show daily rainfall distributons stratified by rainfall instensity and hour of occurrence at various stations studied. The frequency of occurrences independently of mean rainstorm intensity are summarized at the end of the table in the line identified as Totals. Stratification by intensity show preferred time of various intensities to occur. It is interesting to notice that the most intense rainfall occur at the higher frequency of rainfall.

Defining two periods during the day, namely, morning and afternoon, three main daily tendencies are observed throughout the island at the stations studied. First, a skewed distribution with the mode in the early to the mid afternoon. Secondly a bimodal distribution with modes at the early morning and

early afternoon, and a multi-modal distribution which appears more a near-uniform distribution. Table 4.1 show a summary of the tendencies

Table 4.1 Rainfall Station Classified by Type of Tendency

Station	Tendency	Skewed	Bimodal	Multi-Modal
Botijas 2 - Orocovis			*	
Cayey 1E				*
Corozal			*	
Dos Bocas		*		
Fajardo			*	
Maricao 2 SSW		*		
Ponce 4 E				*
San Juan WSFO			*	
San Sebastián 2WNW		*		
Yabucoa 1 NNE				*

The table exhibits a tendency of dryer stations to show multi-modal distributions. Stations located in areas of extremely high intensity rainfall show a skewed unimodal distribution with the mode in the early to mid afternoon. Bimodal distributions are typical of those stations located in areas of moderate rainfall.

Intensity-duration-frequency analysis was performed on storm data in order to determine approximate frequencies of various storm events. Partial duration series of the first forty values were selected to define the base value of the partial duration series.

Intensity-duration-frequency tables are presented in Tables A5 to A14. One table is presented for each station and durations form 1 hour to 5 hours. Other durations are considered non-reliable for the purpose of this study.

Intensity-duration-frequency results at various stations are limited by the number of years of records available (e. g., from 12 to 17 years). However, this results are relevant for return periods of up to approximately 25 years. They also serve as a check for design criteria in Tehcnical Paper # 42 (NWS, 1961).

Results are also limited by the absence of extremely high frequencies typical of hurricane rainfall because limited number of them have occurred during the preiod of record. However, these type of events usually have frequencies longer than 25 years.

Due to the limitations of the data, frequency analysis was performed in a partial duration seires of the total hourly data independent of storm events. The results are compared with rainstorm events.

Tables A15 to A24 show results of hourly data. The table show order rank, date and time of occurrence, total precipitation in inches, exceedance probability in %, and return period in years for all stations studied. Intensity in in/hr is exactly equal to the precipitation depth in inches.

Results show that higher intensities are experienced when rainfall periods are taken independently of storm events. Rainburst within storms show larger results, however, the results show significant differences which obviously will affect hydro-

logic design. For example, Orocovis station shows 1.50 in/hr for a return period of 12.5 years when storm data is used. An approximately 2.50 in/hr is shown for the same return period when hourly data is used. Discrepancies in the length of record is because hourly data considers all the record available, while storm data was selected for the period with storm showing mean intensities higher than 0.20 in/hr.

The results in the tables show relevant discrepancies with Technical Paper #42 from the National Weather Bureau (1961). The topic deserves further study. Since frequency analysis is beyond the scope of this research work, tables are shown for information purposes. Frequency analysis is under study by this researcher and detailed analyses will be available in the near future.

5. CONCLUSIONS:

1. Storm rainfall in Puerto Rico shows temporal distribution tendencies which depend on the location, storm duration, and class of storm (meaning media, tercile or quartile storms). Typical temporal storm rainfall distributions are found in Figures A1 to A10.
2. Temporal storm rainfall distributions show that there is a storm preference to produce more rainfall during a specific period of the storm (e.g. a given quartile). These preferences are identified by the mode in Table A1.
3. Spatial variabilities of temporal storm rainfall distributions are significantly larger as the storm duration increases.
4. The probability of mean storm intensities decreases as the intensity increases. An exponential decay appears to be suitable for describing mathematically the relationship.
5. The probability of storm duration shows approximately an exponential decay similar to the one stated previously in 4.
6. A more comprehensive model can estimate the probability of storm events based on duration and intensity.
7. Storm selection criteria (e.g., minimum time between storms of 6 hours) does affect the frequency distribution of storms. This is because a combined effect of storm merging in time and storm elimination because a reduction in storm intensities. This is particularly true for storms with durations shorter than approximately 12 hours.
8. Mean rainstorm intensities in Puerto Rico for storm events of longer durations than 12 hours show that they are low relative to other storms of shorter durations.

9. Daily rainfall distributions show preferred time of occurrence. Typical tendencies are summarized in Table 4.1. The type of distribution is apparently related to hydrological zones.
10. Limited consideration in intensity-duration-frequency analysis show that large discrepancies exist when storm data vs. interval data is used.
11. The hydrologic design criteria recommended by the Technical Paper #42, (NWB, 1961) need to be updated with real rainfall data analysis.

6. FURTHER RESEARCH WORK:

The research work discussed previously has shown the need for further research work on the topic. The writer has continued his efforts to complete some necessary tasks which were not within the scope of the research work discussed previously. A brief description of the writer's continuing research efforts are in the following:

1. Analysis of remaining rainfall stations not considered in the study.
2. Development of non-dimensional storm rainfall distribution for a minimum storm selection time of 6 hrs between storms.
3. Frequency analysis including intensity-duration-frequency model fitting to the data and updating hydrologic design criteria for storm selection.
4. Evaluation of 15-minute rainfall data
5. Development of interpolation schemes for ungaged sites taking into consideration orographic effects.

APPENDIX B

Inverse Distance Technique for Geographical Interpolation

APPENDIX B

The increase distance technique for geographical interpolation has been discussed in the literature (Pagán-Trinidad, 1982). It states that if certain property P which is measured at various points i, interpolation of the property at points j within the known points can be achieved by taking a weighed mean of the property at the surrounding stations. The weight to each point is given inversely proportional to the distance between points i and j. Mathematically it can be expressed as follows:

$$P_j = \frac{\sum(P_i / L_i^x)}{\sum(\frac{1}{L_i^x})} \quad \text{B.1}$$

where

P_j = property (e.g., precipitation) at point j

P_i = property (e.g., precipitation) at point i

L_i = distance between points i and j

x = exponent

Storm rainfall distribution can be interpolated in space by repeating the spatial interpolation for various points in the non-dimensional curve. L_i can be determined by applying the inverse geodesic problem (Hosmer, 1946; Bonford, 1952; Ewing and Mitchell, 1970).

APPENDIX C

Examples of Various Computer Data Files Availables Upon Request

Appendix C

Various computer files containing reduced rainfall data from the stations analyzed are available from the study. They are not included in the report because of their extension. However, considering that most of the practicing engineers and some government agencies do not have computer facilities capable of reproducing the work, they will be kept temporarily and they can be furnished to the reader upon request at the cost of duplication, shipping and handling. Samples of computer outputs which are considered of importance for practicing engineers are:

1. Table C1: Listing of Rainstorm Data. It includes beginning and ending time of storm (hour and date), duration in hours, total storm rainfall in inches, and mean rainfall intensity in in/hr for storms with mean storm rainfall intensity greater or equal to 0.20 in/hr. There is one file per station with storms organized in chronological order for both rainstorm selection criteria: 1-hr and 6-hr minimum time between storms.
2. Table C2: Storm Hyetographs Stratified by Station and Storm Duration. It includes beginning and ending time and data of significant storms, duration in hours, total rainfall in inches and mean storm intensity in in/hr. Hourly rainfall in inches and percentage of total storm rainfall. It also includes the cumulative percentage of storm depth. The file contains all the significant storms at each station classified by durations. The mean non-dimensional distribution for each storm duration is presented at the end of the table. The standard deviation of the values at each selected percentage is presented.
3. Table C3: Statistics of Non-Dimensional Storm Rainfall Distributions. It presents basic statistics for storm rainfall distributions stratified by station storm duration, and storm

class withing the given duration. Basic statistics include mean, standard deviation, shewness, kurtosis, coefficient of shewness, and coefficient of kurtosis for each point estimated in the distribution (e.g., 10%, 20%, etc). The mean non-dimensional storm rainfall distributions are also shown.

Other computer outputs which are available but not shown in the Appendix are:

1. Frequencies of Storm Rainfall Stratified by Storm Duration and Mean Storm Rainfall Intensities: A summary of this file is shown in Tables A2 and Table A3. The file shows various basic statistics which are not shown in the tables. The computer output is stratifies rainfall intensities at 0.10 in/hr intervals, instead of defining variable class intervals.
2. A computer program was written in BASIC for the interpolation technique described in Appendix C. Copies of the computer program will be available to users.
